## Abstract

Atmospheric deposition of Pu isotopes from the Fukushima Daiichi Nuclear Power Plant (FDNPP) accident has been observed in the terrestrial environment around the FDNPP site; however, their deposition in the marine environment has not been studied. The possible contamination of Pu in the marine environment has attracted great scientific and public concern. To fully understand this possible contamination of Pu isotopes from the FDNPP accident to the marine environment, we collected marine sediment core samples within the 30 km zone around the FDNPP site in the western North Pacific about two years after the accident. Pu isotopes ( $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ , and  $^{241}\text{Pu}$ ) and radiocesium isotopes ( $^{134}\text{Cs}$  and  $^{137}\text{Cs}$ ) in the samples were determined. The high activities of radiocesium and the  $^{134}\text{Cs}/^{137}\text{Cs}$  activity ratios with values around 1 (decay corrected to 15 March 2011) suggested that these samples were contaminated by the FDNPP accident-released radionuclides. However, the activities of  $^{239+240}\text{Pu}$  and  $^{241}\text{Pu}$  were low compared with the background level before the FDNPP accident. The Pu atom ratios ( $^{240}\text{Pu}/^{239}\text{Pu}$  and  $^{241}\text{Pu}/^{239}\text{Pu}$ ) suggested that global fallout and the Pacific Proving Ground (PPG) close-in fallout are the main sources for Pu contamination in the marine sediments. As Pu isotopes are particle-reactive and they can be easily incorporated with the marine sediments, we concluded that the release of Pu isotopes from the FDNPP accident to the marine environment was negligible.

## 55    **Introduction**

56        On 11 March 2011, a massive earthquake with a magnitude of M 9.0 occurred in the  
57        western North Pacific about 180 km off the Fukushima Daiichi Nuclear Power Plant (FDNPP)  
58        in the northeast coast of Japan and it was followed by gigantic tsunami. As a result, power  
59        supplies were lost at the FDNPP and core cooling could not be carried out. This led to  
60        pressure buildups which were relieved in venting actions by operators and by hydrogen  
61        explosions. Consequently, large amounts of radionuclides were released into the environment.  
62        Extensive studies about the distributions and human health impacts of the volatile fission  
63        products, such as  $^{90}\text{Sr}$ ,  $^{131}\text{I}$ ,  $^{134}\text{Cs}$ , and  $^{137}\text{Cs}$  in the environment after the accident have been  
64        conducted<sup>1-5</sup>. However, only limited studies have focused on the nonvolatile Pu isotopes in  
65        the environment. Pu isotopes present a high risk for internal radiation exposure via ingestion  
66        of contaminated agricultural crops and seafood products and are important for long-term dose  
67        assessment due to their long half-lives<sup>6,7</sup>. In the FDNPP, Pu isotopes were produced in the  
68        reactor units which used uranium-based nuclear fuels and especially in the Unit 3 reactor,  
69        where 32 mixed-oxide fuel assemblies containing ~6% Pu were initially loaded<sup>8</sup>. Thus  
70        information about the release of Pu isotopes in the environment is also important to  
71        understand the reactor core damages.

72        The FDNPP accident introduced radioactive contamination into the marine environment  
73        through the deposition of the radionuclides released into the atmosphere as well as through

74 the direct discharge of thousands of tons of radioactive liquid waste<sup>9,10</sup>. As marine products  
75 play an important role in the Japanese diet, seafood safety has attracted considerable public  
76 and scientific concern. In the terrestrial environment around the FDNPP site, the Pu isotopes  
77 released from the accident were detected in soil, litter, dust and aerosol samples after the  
78 accident and the total released amounts of Pu isotopes were estimated<sup>11-14</sup>. However, the  
79 amount of Pu isotopes directly released into the marine environment remains unknown. In the  
80 high level radioactive accumulated water collected at the FDNPP after the accident, high  
81 level radioactivities of Pu isotopes were detected ( $(5.8-13) \times 10^{-2}$  Bq mL<sup>-1</sup> for <sup>238</sup>Pu,  
82  $(3.0-7.2) \times 10^{-2}$  Bq mL<sup>-1</sup> for <sup>239+240</sup>Pu,  $(1.7-3.2) \times 10^{-2}$  Bq mL<sup>-1</sup> for <sup>241</sup>Pu; decay corrected to 19  
83 January 2012)<sup>15</sup>. These values were 6 to 7 orders of magnitudes higher than that of the  
84 seawater in the western North Pacific. Thus attention should be paid to the contamination  
85 situation of Pu isotopes in the marine environment off Fukushima since the FDNPP accident.

86 We previously studied Pu distributions in marine sediments and seawater samples collected  
87 in the western North Pacific 30 km off the FDNPP site within a few months to about two  
88 years after the accident and we observed no detectable Pu contamination from the FDNPP  
89 accident in the investigated areas<sup>16-20</sup>. Radiocesium isotopes from the accident have been  
90 widely observed in the marine sediments off Fukushima after the accident<sup>2,21,22</sup>. Pu isotopes  
91 are more particle-reactive than radiocesium and the sediment-water distribution coefficient  
92 ( $K_d$ ) of Pu in the marine environment is  $1 \times 10^5$ , two orders of magnitudes higher than that of

93  $\text{Cs}^{23,24}$ . In Irish Sea, where has been contaminated by the discharged liquid radioactive waste  
94 from Sellafield nuclear fuel reprocessing plant, Mitchell et al.<sup>25</sup> found that the concentrations  
95 of Pu isotopes in the seawater and sediment declined with an availability time of ca. 100 y,  
96 which was at least one order of magnitude longer than that of  $^{137}\text{Cs}$ . Thus the possible  
97 FDNPP-released Pu isotopes in the marine environment could be more easily incorporated  
98 with the marine sediments and kept there for a long time. Recently Perianez et al.<sup>26</sup> modeled  
99 that if the discharge of Pu from the FDNPP accident occurred in the marine environment, it  
100 would remain within the 30 km zone around the FDNPP site. Therefore, the Pu isotopes in  
101 the marine sediments in the near coastal areas of Fukushima need to be investigated.

102 Pu atom ratios ( $^{240}\text{Pu}/^{239}\text{Pu}$  and  $^{241}\text{Pu}/^{239}\text{Pu}$ ) are used as powerful fingerprints for Pu source  
103 identification, as they are known to vary among different sources<sup>27</sup>. The Pu isotopes derived  
104 from the accident have been characterized by a high  $^{240}\text{Pu}/^{239}\text{Pu}$  ( $> 0.3$ ) atom ratio<sup>11-14</sup>, which  
105 makes it easy to distinguish them from global fallout ( $^{240}\text{Pu}/^{239}\text{Pu}$  atom ratio = 0.18) in the  
106 terrestrial environment<sup>28</sup>. For the marine sediments, however, Pu isotopes around the FDNPP  
107 site could be attributed to global fallout and the Pacific Proving Ground (PPG) close-in  
108 fallout, which was transported by the oceanic currents from the nuclear weapon test sites in  
109 the Marshall Islands to the western North Pacific before the 2011 accident<sup>29,30</sup>. The FDNPP  
110 accident-derived  $^{240}\text{Pu}/^{239}\text{Pu}$  atom ratio is higher than the global fallout ratio (0.18) but  
111 similar to that (0.30-0.36) of the PPG source<sup>11,14,29,31</sup>. Thus the determination of another

112 fingerprint  $^{241}\text{Pu}/^{239}\text{Pu}$  atom ratio is strongly needed for distinguishing Pu sources in the  
113 marine sediments. The  $^{241}\text{Pu}/^{239}\text{Pu}$  atom ratio (0.083-0.135)<sup>11,14</sup> of the FDNPP accident  
114 released Pu is almost two orders of magnitude higher than both the global fallout (0.0011)<sup>28</sup>  
115 and the PPG source (*ca.* 0.0020)<sup>32,33</sup> values ( $^{241}\text{Pu}$  decay corrected to 15 March 2011).  
116 However, the  $^{241}\text{Pu}$  activity in the marine sediments is currently very low ( $< 5 \text{ mBq g}^{-1}$ ) due  
117 to its short half-life (14.4 y), which makes it difficult to measure. Thanks to our established  
118 sensitive analytical methods based on anion-exchange chromatography and sector field  
119 ICP-MS,  $^{241}\text{Pu}$  in the marine sediments can be accurately analyzed with sample amounts over  
120  $10 \text{ g}^{18}$ .

121 In this work, we collected marine sediment samples within the 30 km zone around the  
122 FDNPP site about two years after the accident to investigate the Pu distribution in the near  
123 coastal marine environment off Fukushima. Pu activities ( $^{239+240}\text{Pu}$  and  $^{241}\text{Pu}$ ) and atom ratios  
124 ( $^{240}\text{Pu}/^{239}\text{Pu}$  and  $^{241}\text{Pu}/^{239}\text{Pu}$ ) were determined to give a more comprehensive conclusion  
125 about the possible Pu contamination from the FDNPP accident. The radiocesium activities  
126 ( $^{134}\text{Cs}$  and  $^{137}\text{Cs}$ ) and  $^{134}\text{Cs}/^{137}\text{Cs}$  activity ratio in these sediment samples were also measured.

127

## 128 **Methods**

### 129 **Sediment sampling**

130 Sediment core sampling locations (NP2, 37°25.00'N 141°06.00'E; NP1, 37°25.00'N

141°10.70"E; AN6, 37°16.74'N 141°05.34"E; M01, 37°33.00'N 141°13.08"E; I02, 37°14.00'N  
141°13.08"E) were in the western North Pacific within the 30 km zone around the FDNPP  
site. Collection was done with a sediment multiple corer during the UM 13-05 cruise (T/S  
Umitaka-maru, Tokyo University of Marine Science and Technology) in May 2013. The  
closest collection location (NP2) was *ca.* 5 km off the FDNPP site. The core samples were cut  
into 1 cm segments and stored in an on-board refrigerator until they were brought back to the  
land-based laboratory. The locations of the sampling sites within the 30 km zone around the  
FDNPP site of this study and of the sampling sites outside the 30 km zone in our previous  
studies<sup>17,18,20</sup> are shown in Fig. 1.

#### **Analytical procedure for radiocesium and Pu isotopes**

The sediment samples were first dried at 105 °C for 24 h. The activities of <sup>134</sup>Cs and <sup>137</sup>Cs  
were measured by gamma-ray spectrometry using an HPGe detector (GX-2019, Canberra)  
and the detection limit was *ca.* 1 mBq g<sup>-1</sup>. The activities of radiocesium in the sediments were  
decay corrected to the sampling date. After the measurement of radiocesium, sediment  
samples were ashed in a microwave muffle furnace at 450° C for 5 h to destroy the organic  
matter. The ignition losses of the samples were calculated from the weights before and after  
the ashing procedure.

About 2-40 g of dried sediment samples were weighed out for Pu analysis. The sample

150 preparation procedures for Pu analysis were based on our previous work<sup>18</sup> and are illustrated  
151 in Fig. S1. Briefly, a sediment sample and 20-40 mL concentrated HNO<sub>3</sub> were put in a Teflon  
152 vessel (120 mL) which was then tightly closed. Digestion was done on a hot plate at 160 °C  
153 for at least 4 h. Then the sample solution was filtered and its acidity was adjusted to that of 8  
154 M HNO<sub>3</sub>. NaNO<sub>2</sub> was added to the sample solution to a concentration of 0.2 M and the  
155 mixture was heated at 40 °C for 30 min to take Pu to the tetravalent state. After  
156 preconditioning the AG 1X8 resin column with 20 mL 8 M HNO<sub>3</sub>-0.2 M NaNO<sub>2</sub>, the sample  
157 solution was loaded onto the column. 50 mL 8 M HNO<sub>3</sub> was used for the washing of U, Pb  
158 and Fe and 30 mL 10 M HCl was used for the washing of Th from the column and converting  
159 the resin back to the chloride form. Then Pu was eluted with 40 mL 0.1 M NH<sub>4</sub>I-8.5 M HCl.  
160 The eluent was evaporated to near dryness in a 100 mL Teflon beaker. 1 mL *aqua regia* was  
161 added and the mixture was heated to dryness; this addition of acid and heating was repeated a  
162 second time to destroy the organic matter and remove the residual iodine. Then 2 mL  
163 concentrated HCl was added and the mixture was evaporated to dryness once more. After  
164 adding 4 mL of freshly prepared HCl-H<sub>2</sub>O<sub>2</sub> and heating at 40 °C for 30 min, the sample  
165 solution was ready for loading onto the second AG MP-1 M resin column. The second resin  
166 column was preconditioned with 8 mL HCl-H<sub>2</sub>O<sub>2</sub> and then the sample solution was loaded  
167 onto it. 20 mL 8 M HNO<sub>3</sub> and 8 mL HCl were used for the further washing of U and Th,  
168 respectively. Pu was eluted from the AG MP-1 M resin with 16 mL concentrated HBr and the

169 eluant was collected in a 30 mL Teflon beaker. After evaporating the sample solution to near  
170 dryness, 1 mL concentrated HNO<sub>3</sub> was added and this was heated to near dryness to remove  
171 HBr. The final residue was dissolved in 0.8 mL 4% HNO<sub>3</sub> in preparation for analysis. All  
172 reagents were superpure grade and all the water that we used was treated with a Milli-Q water  
173 system (>18.0 MΩ).

174 The analysis of Pu isotopes was performed on a SF-ICP-MS (Element 2, Thermo Finnigan,  
175 Bremen, Germany). When combined with an APEX-Q high efficiency sample introduction  
176 system, the sensitivity of the SF-ICP-MS was between 1.0-1.5×10<sup>7</sup> cps ppb<sup>-1</sup> for <sup>238</sup>U<sup>+</sup>. The  
177 detailed operational setup and parameters of this analytical system were described  
178 elsewhere<sup>34</sup>. A certified Pu isotope standard solution (NBS-947) was used for mass bias  
179 correction and two marine sediment standard reference materials IAEA-368 and NIST-4357  
180 were used for the analytical method validation. Fig. 2 shows typical spectra of the marine  
181 sediments and the operational blank of the method. Using our Pu separation procedure and  
182 analysis system, we can sufficiently remove U interference from the sediment sample matrix  
183 and Pu isotopes can be reliably determined<sup>18</sup>.

## 185 Results and discussion

186 The results for Pu and radiocesium isotopes in the marine sediments within and outside the  
187 30 km zone around the FDNPP site are summarized in Table 1. The vertical distributions of

Pu and radiocesium isotopes and the ignition losses at sampling locations NP2, NP1, AN6, I02 and M01 are illustrated in Fig. 3. More detailed analytical results are summarized in Table S1 and S2.

### **Radiocesium contamination in the marine sediments**

$^{134}\text{Cs}$  and  $^{137}\text{Cs}$  are two of the major radionuclides released from the FDNPP accident into the environment. It has been estimated that the total atmospheric release of  $^{137}\text{Cs}$  from the accident was 9.9-36 PBq and more than 70% was deposited in the ocean<sup>7,35-37</sup>. In addition, 2.3-27 PBq  $^{137}\text{Cs}$  was directly released to the sea<sup>10,38,39</sup>. Although Cs is regarded as a “soluble” element in the marine environment, it can be selectively absorbed by clay minerals and subsequently deposited on the seafloor.

The activities of  $^{134}\text{Cs}$  and  $^{137}\text{Cs}$  in the sediments investigated in this study ranged from 3.0 to 78.4 mBq g<sup>-1</sup> and from 7.2 to 154.9 mBq g<sup>-1</sup>, respectively (decay corrected to the sampling date). These values are significantly higher than that of the background level (0-2 mBq g<sup>-1</sup> for  $^{137}\text{Cs}$  in the surface sediments off Fukushima in 2010) before the FDNPP accident<sup>40</sup>. Kusakabe et al.<sup>2</sup> studied the distribution of radiocesium in marine sediments collected 30 km off Fukushima in 2011 and 2012, and they found that the activities of  $^{137}\text{Cs}$  in the surface sediments ranged from 1.7 to 580 mBq g<sup>-1</sup>. Our results for the sediments within the 30 km zone around the FDNPP site were within their reported concentration range. The highest

activity of radiocesium in the sediment cores was observed at location I02 southeast of the FDNPP site. It has been simulated that the contaminated water released from the FDNPP accident had generally flowed southward from the adjacent area of the FDNPP site in March and April 2011<sup>10</sup>, which could lead to higher deposition of radiocesium at location I02 than at other locations even though I02 was the furthest from the FDNPP site among all the sampling locations in this study. Moreover, the sediments collected at I02 had a higher percentage of silt and contained a higher amount of organic matter than sediments collected at the other locations, which would lead to them incorporating more radiocesium from the seawater.

The FDNPP-released radiocesium was characterized by a  $^{134}\text{Cs}/^{137}\text{Cs}$  activity ratio of 1 on 15 March 2011<sup>37,41</sup>. In our study, the  $^{134}\text{Cs}/^{137}\text{Cs}$  activity ratios for the sediments ranged from 0.82 to 1.24 with an average of  $0.99 \pm 0.07$  (Fig. 4), clearly indicating that these sediments were contaminated with radiocesium from the FDNPP accident. The inventories of radiocesium in the sediment core samples were shown in Table S1. The inventories (0-10 cm) of  $^{134}\text{Cs}$  and  $^{137}\text{Cs}$  ranged from 743 to 11162 Bq m<sup>-2</sup> and from 1663 to 18867 Bq m<sup>-2</sup>, respectively, not significantly higher than that reported for the sediments collected 30 km off the FDNPP site<sup>2,21,22</sup>. The ratios of radiocesium inventories in the surface layers (0-3 cm) to that in the whole sediment cores (0-10 cm) ( $F_{0-3}$ ) ranged from 0.19 to 0.54. Otosaka et al.<sup>21,22</sup> also reported that for the sediments in the shallow depth of 100 m in the coastal areas of Ibaraki and Fukushima, the  $F_{0-3}$  values of radiocesium were less than 0.5.

## Vertical distribution of Pu activities and inventories

In previous studies<sup>17,18,20</sup>, we determined the distribution of Pu isotopes in the marine sediments collected 30 km off Fukushima and we found that there was no detectable Pu contamination originating from the FDNPP accident. The  $^{239+240}\text{Pu}$  and  $^{241}\text{Pu}$  activities in the sediment cores within the 30 km zone around the FDNPP site ranged from 0.25 to 0.97 mBq  $\text{g}^{-1}$  and from 0.31 to 1.12 mBq  $\text{g}^{-1}$ , respectively (Table S2), typically lower than that of the sediments collected outside the 30 km zone as summarized in Table 1. The  $^{239+240}\text{Pu}$  activities were comparable with the values (0.7-1.0 mBq  $\text{g}^{-1}$ ) observed in the surface marine sediments off Fukushima in 2008-2010 before the accident<sup>42</sup>.  $^{241}\text{Pu}$  is regarded as a more sensitive indicator for the recently released Pu as the background level of  $^{241}\text{Pu}$  in the environment is currently very low due to its short half-life (14.4 y). In a location (37°12'N, 141°20'E) close to I02, a  $^{241}\text{Pu}$  activity of 0.99 mBq  $\text{g}^{-1}$  was reported in the surface sediment in 2008, which was similar with the results we found at location I02 and higher than that observed at other locations<sup>42</sup>. These results suggested that there were no abnormal values for Pu concentration in the sediments collected within the 30 km zone around the FDNPP site.

In the marine environment with a high sedimentation rate, usually a subsurface Pu activity maximum corresponding to the year of 1963, when the largest global fallout Pu occurred, can be observed<sup>43</sup>. However, in Fig. 3, both the  $^{239+240}\text{Pu}$  and  $^{241}\text{Pu}$  activities were almost constant

245 in each sediment core from the surface to the investigated depth and no distribution peaks  
246 could be found. As most of the sediments were sandy with low organic matter content, the  
247 bioturbation effect in the sediments was low. Thus the strong coastal current and the  
248 earthquake and tsunami happened in March 2011 could be the main reasons that led to the  
249 sufficient mixing of Pu in these sediments. The inventories of  $^{239+240}\text{Pu}$  at NP2 (0-10 cm),  
250 NP1 (0-3 cm), AN6 (0-14 cm), M01 (0-7 cm) and I02 (0-10 cm) were calculated to be 52.3,  
251 13.7, 119.3, 37.3 and 102.6 Bq m<sup>-2</sup>, respectively, and they were comparable with that of the  
252 sediments outside the 30 km zone around the FDNPP site observed in our previous study<sup>17</sup>.  
253 The inventories of  $^{241}\text{Pu}$  at NP2 (0-10 cm), NP1 (0-3 cm) and I02 (0-10 cm) were 66.0, 16.6  
254 and 126.4 Bq m<sup>-2</sup>, respectively. These values are the first reports for vertical distributions of  
255  $^{241}\text{Pu}$  in the marine sediments in the western North Pacific.

256

#### 257 **Distribution of Pu atom ratios and Pu source identification**

258 Pu atom ratios ( $^{240}\text{Pu}/^{239}\text{Pu}$  and  $^{241}\text{Pu}/^{239}\text{Pu}$ ) have been regarded as powerful fingerprints  
259 for Pu source identification. In soil and litter samples obtained around the FDNPP site, Zheng  
260 et al.<sup>11</sup> observed that the accident-released Pu isotopes were characterized by high  $^{240}\text{Pu}/^{239}\text{Pu}$   
261 (0.30-0.33) and  $^{241}\text{Pu}/^{239}\text{Pu}$  (0.103-0.135) atom ratios. Shinonaga et al.<sup>14</sup> determined Pu  
262 isotopes in aerosol samples collected 120 km from the plant site a few days after the accident  
263 and they found similar Pu atom ratios ( $0.32 \pm 0.10$  for  $^{240}\text{Pu}/^{239}\text{Pu}$  and  $0.117 \pm 0.032$  for

<sup>241</sup>Pu/<sup>239</sup>Pu) in these samples. These Pu isotopic composition values could be considered as the indicator for the FDNPP-derived Pu. The <sup>240</sup>Pu/<sup>239</sup>Pu and <sup>241</sup>Pu/<sup>239</sup>Pu atom ratios in the marine sediments within the 30 km zone around the FDNPP site showed very small variations, ranging from 0.233 to 0.258 and from 0.0012 to 0.0016, respectively. In Fig. 5, we plotted the Pu atom ratios in the sediments within 30 km zone around the FDNPP site, in the surface sediments outside the 30 km zone and in other sources. The values for Pu isotopes in the Fukushima marine sediments within the 30 km zone around the FDNPP site were far from the mixing line between global fallout and the FDNPP source but along the mixing line between global fallout and the PPG source. This result suggested that global fallout and the PPG close-in fallout were still the two main sources for Pu contamination in the marine sediments in the near coastal areas of Fukushima after the accident.

The Fukushima accident-derived Pu isotopes were evidenced in the terrestrial environment. The total amount of <sup>239+240</sup>Pu released into the atmosphere was estimated to be  $1.0\text{--}3.5 \times 10^9$  Bq, which was four orders of magnitudes lower than that of the Chernobyl accident<sup>6,13</sup>. If we assume that half of these Pu isotopes deposited in the sea around the FDNPP site in a circle with a radius of 100 km and all finally incorporated into the corresponding marine sediments. We can estimate that the extra inventory of <sup>239+240</sup>Pu was *ca.* 0.1 Bq m<sup>-2</sup>; this amount of <sup>239+240</sup>Pu input was negligible compared to the inventory of <sup>239+240</sup>Pu (around 100 Bq m<sup>-2</sup>) in the marine sediments before the accident. Therefore, the contamination of Pu isotopes in the

283 marine environment from the FDNPP accident through atmospheric deposition could be  
284 small considering the dilution effect of seawater. The direct discharge of radioactive liquid  
285 waste should be the main way for possible Pu contamination from the FDNPP accident to the  
286 marine environment. However, very limited information is available regarding Pu  
287 concentration in the directly discharged radioactive liquid waste from the accident. In our  
288 previous study<sup>19</sup>, we investigated the Pu distribution in seawater samples (collected from  
289 May 2011 to January 2013) in the western North Pacific after the FDNPP accident and found  
290 that both the  $^{239+240}\text{Pu}$  activities and  $^{240}\text{Pu}/^{239}\text{Pu}$  atom ratios were in the range of the  
291 background values before the accident. As the Pu isotopes are particle-reactive and they can  
292 be easily incorporated by sinking particles, Pu distribution in the near coastal marine  
293 sediments can give direct information about Pu contamination in the marine environment. As  
294 no detectable Pu isotopes from the FDNPP accident could be identified in the marine  
295 sediments within the 30 km zone in this study, we concluded that the release of Pu isotopes  
296 from the FDNPP accident to the marine environment was negligible compared with the  
297 background levels. Global fallout and the PPG close-in fallout are the two main sources for  
298 Pu contamination in the marine environment before and after the FDNPP accident.

299 It can be seen in Fig. 5, the  $^{240}\text{Pu}/^{239}\text{Pu}$  and  $^{241}\text{Pu}/^{239}\text{Pu}$  atom ratios in the surface marine  
300 sediments collected outside the 30 km zone around the FDNPP site were slightly lower than  
301 that of the sediments collected within the 30 km zone around the FDNPP site. However, high

Pu atom ratios ( $^{240}\text{Pu}/^{239}\text{Pu} > 0.27$ ) have been commonly observed in the deeper layer sediments outside the 30 km zone due to the direct deposition of the PPG close-in fallout<sup>17</sup>. As discussed before, the strong physical sedimentation mixing process in the near coastal marine environment resulted in the constant distribution of Pu atom ratios in the marine sediments within the 30 km zone around the FDNPP site. Based on a simple two-end-member mixing model<sup>44</sup>, we calculated the inventory-weighted contributions of these two sources for Pu distribution in the marine sediments investigated in this study. Global fallout and the PPG close-in fallout contributed  $47\pm 3\%$  and  $53\pm 3\%$ , respectively to the Pu contamination in the marine sediments within the 30 km zone around the FDNPP site. The results were similar to the results ( $38\text{--}43\%$  for the PPG close-in fallout and  $62\text{--}57\%$  for global fallout) we observed in the western North Pacific outside the 30 km zone around the FDNPP site<sup>20</sup>.

In this study, for the first time, we investigated the distribution of Pu activities ( $^{239+240}\text{Pu}$  and  $^{214}\text{Pu}$ ) and Pu atom ratios ( $^{240}\text{Pu}/^{239}\text{Pu}$  and  $^{241}\text{Pu}/^{239}\text{Pu}$ ) in sediment core samples collected in the western North Pacific within the 30 km zone around the FDNPP site after the March 2011 accident. We provided new information for a better understanding of the influence of the FDNPP accident on Pu contamination in the marine environment. We found that the release of Pu isotopes from the accident to the marine environment was negligible to date. Pu isotopes in the marine sediments originated from global fallout and PPG close-in fallout. However, in the water intake position of the reactor unit 1,  $^{238}\text{Pu}$  and  $^{239+240}\text{Pu}$

activities were found to be 0.21 mBq g<sup>-1</sup> and 1.2 mBq g<sup>-1</sup> in the surface sediment in July 2011, respectively, two to three times higher than those in the sediment before the accident<sup>45</sup>. The <sup>238</sup>Pu/<sup>239+240</sup>Pu activity ratio of 0.175 was also higher than that (0.037) of the global fallout material in Japan<sup>46</sup>. These results revealed the local deposition of the FDNPP derived Pu in that region although the Pu activities were still relatively low. Presently, 270,000 tons of radioactive liquid waste are stored in large tanks within the FDNPP site boundary and the total amounts of <sup>238</sup>Pu, <sup>239+240</sup>Pu and <sup>241</sup>Pu contained in this were estimated to be 3×10<sup>8</sup> Bq, 1×10<sup>8</sup> Bq and 1×10<sup>10</sup> Bq, respectively<sup>47</sup>. Future earthquakes and other unexpected events could cause leakage of this stored liquid waste and introduce new Pu contamination into the sea. Therefore, Pu isotopes in the marine environment, especially in the trench or very local coastal site near the FDNPP site should be continuously investigated.

## Figure Captions

**Figure 1.** Map showing the locations for: (a) sediment samples collected within the 30 km zone around the FDNPP site in this study and (b) sediment samples collected outside the 30 km zone around the FDNPP site in our previous studies (redrawn from Zheng et al.<sup>16</sup> and Bu et al.<sup>17,18,20</sup>).

**Figure 2.** Typical mass spectra of (a) an operational blank and (b) a sediment sample analyzed by our method. <sup>242</sup>Pu was used as chemical yield tracer.

**Figure 3.** Vertical distributions of <sup>137</sup>Cs activities, <sup>239+240</sup>Pu activities, <sup>241</sup>Pu activities, <sup>134</sup>Cs/<sup>137</sup>Cs activity ratios, <sup>240</sup>Pu/<sup>239</sup>Pu atom ratios and <sup>241</sup>Pu/<sup>239</sup>Pu atom ratios in the sediment core samples.

**Figure 4.** Results of <sup>137</sup>Cs activities and <sup>134</sup>Cs/<sup>137</sup>Cs activity ratios in the marine sediments (decay corrected to 15 March 2011). The blue dashed line represents the <sup>134</sup>Cs/<sup>137</sup>Cs activity ratio fingerprint of the FDNPP accident released radiocesium.

**Figure 5.** Mixing plot of <sup>241</sup>Pu/<sup>239</sup>Pu atom ratio vs. <sup>240</sup>Pu/<sup>239</sup>Pu atom ratio in the Fukushima sediments, comparison with the Pu compositions of global fallout, FDNPP release, and the PPG close-in fallout. The closed orange circles (soil and litter samples, cited from Zheng et al.<sup>11</sup>) and closed black circles (aerosol samples, cited from Shinonaga et al.<sup>14</sup>) represent the FDNPP source; the closed pink circle represents the global fallout (cited from Kelley et al.<sup>28</sup>); the closed blue circles represent the surface sediment samples collected outside the 30 km zone (cited from Bu et al.<sup>18</sup>); the open black circles represent the vertical distributed sediment samples within the 30 km zone; the closed violet circle represents the Sagami Bay sediment sample (cited from Zheng and Yamada<sup>48</sup>); the closed wine circles represent the PPG source (cited from Yamamoto et al.<sup>32</sup> and Lachner et al.<sup>33</sup>).
